RESULTS OF THE KENTUCKY SMALL GRAIN VARIETY TRIALS IN 1968

C. R. Tutt, V. C. Finkner and R. H. Loe

The purpose of the Kentucky small grain variety trials is to evaluate varieties of wheat, oats and barley which are commercially available or may soon be available to Kentucky farmers. New varieties are continuously being developed by the Kentucky Agricultural Experiment Station and other state experiment stations and commercial firms. New varieties that appear to have desirable characteristics are evaluated so farmers and agricultural workers may have the information to make an intelligent choice of varieties that best suit their needs.

The average acre yield of small grains in Kentucky in 1968 was wheat, 30 bushels; oats, 40 bushels and barley, 41 bushels per acre. These yields gave a production of 6.2 million bushels of wheat, 0.9 million bushels of oats, and 1.5 million bushels of barley.

The acreage devoted to small grain in Kentucky has been steadily decreasing for the last 20 years. However, yields per acre have been sharply increasing and high-yielding new varieties now deserve more careful consideration in cropping programs. The continued improvement of small grain and new cropping practices such as double cropping should result in small grain playing an increasingly important role in Kentucky agriculture.

EXPERIMENTAL METHODS

In 1968, the wheat, oat and barley variety trials were grown at four locations in the state; Murray, Princeton, Bowling Green, and Lexington. The response of a variety in one area of the state may be quite different from that in another owing to different environmental conditions, soil types and cultural practices. Because of this variability, trials are grown in different areas so that results may be obtained for local conditions.

Data are also collected for a period of years at each location since results vary from year to year. Two- and three-year results give a more accurate picture of performance than do annual data.

The experimental areas at Lexington and Princeton received no fertilizer treatments, and those at Murray and Bowling Green received a broadcast application of a complete fertilizer in the spring before plots were seeded in the fall. All areas were fallowed the previous year, and a green manure legume crop was turned under prior to the fall seeding.

The experimental plots consisted of 4 rows 1 foot apart and 13 feet long. Each variety was grown in four plots placed at random over the test area and the results given in the tables are the average response of the four plots. The plots were planted with a special built four-row seeder, and the data were taken from the two center rows of each plot.

Yield

Yields are taken by cutting 10 feet of the two center rows and threshing the grain through a stationary thresher. The weights of each plot were then converted to bushels per acre.

Lodged

Lodging is reported as the percentage of the total plants that are on the ground or are leaning at a 45-degree angle from the vertical. Lodging is reported when the grain is mature. The term "maturity" as used in this report refers to the date the grain is ready to be harvested.

Plant Height

Plant height is recorded as the number of inches from the ground to the tip of the grain head.

Date Headed

Date headed is reported as the number of days after March 31, at which 50 percent of the heads have emerged from the plants in each plot.

Survival

Survival is recorded as the percentage of plants which are estimated to have survived the winter when fall planted. This is a measure of winterhardiness and is an important factor to consider when selecting a small grain variety.

Test Weight

Test weight, or the weight of a bushel of grain, is a measure of the quality of grain. The higher the test weight the higher the quality and the higher the market value unless the grain has been down-graded because of another quality factor.

INTERPRETATION

In interpreting the results it is important to consider characteristics other than yield before choosing a variety. Factors such as height of straw, lodging resistance, earliness or lateness of maturity and grain quality should be weighted.

Small differences in yield of only a few bushels per acre between two varieties from an individual test should not be interpreted to indicate the superiority of one variety over another. However, if one variety is consistently outyielding another over a period of several years the chances are that the differences are real and should be considered important.

Lodging data are quite difficult to interpret. A high-yielding variety should not necessarily be down-graded because of a high percentage of lodging at a location. Local weather conditions, such as heavy winds and rains, may cause a variety to lodge much worse than it normally does. It should also be emphasized that a variety reported to be lodged 50 percent does not infer that only 50 percent of the grain can be harvested. With good equipment it may be expected that almost all of the grain could be saved. Lodging data for a period of years should receive more consideration than annual lodging data.

The ultimate test for any variety is how it performs on the individual farm. Therefore, to make a sound decision, it is wise to plant a few acres of a new variety and, thus, compare it with those presently used.

Kentucky Agricultural Experiment Station
1968-69 Recommended Small Grain Varieties

Spring Oats

Brave

Certified Seed: Certified seed is seed which has been grown in such a way as to insure the genetic identity and purity of a variety. Certified seed also helps to maintain freedom from weed and other crop seed and, in some cases, freedom from diseases. The Experiment Station recommends that Kentucky certified seed be used whenever possible for growing commercial crops of small grains.
